Abstract

The Hidden Markov model (HMM) is a fundamental tool for sequence modeling that cleanly separates the hidden state from the emission structure. However, this clean separation makes HMMs difficult to fit to large datasets in modern NLP, and they have fallen out of use due to very poor performance compared to fully observed models. This work revisits the challenge of scaling HMMs to supervised datasets, taking ideas from recent approaches to neural modeling. We propose methods for scaling HMMs to massive state spaces, while maintaining compact parameterization, effective regularization, and efficient exact inference. Experiments show that this approach leads to models that are much more accurate than previous HMMs and ngram-based methods while nearing the performance of NN models.

1 Introduction

Hidden Markov models (HMMs) are a fundamental latent-variable model for sequential data. Historically they have been used extensively in NLP for tasks such as sequence modeling (Rabiner, 1990), alignment (Vogel et al., 1996), and even, in a few cases, to language modeling (Kuhn et al., 1994; Huang, 2011). Compared to other approaches for sequence models, HMMs are naturally appealing since they fully separate out the process of sequential memory from the process of generation, while allowing for exact posterior inference.

In recent years, most state-of-the-art systems in NLP have moved away from utilizing latent hidden states and toward deterministic deep neural models. We take several lessons from the success of deep neural models for NLP tasks: (a) the right factorization is critically important for representation learning, e.g. a feedforward model (Bengio et al.,

2003) can have the same probabilistic structure as an n-gram model while performing significantly better; (b) overparameterization is critical for finding better local optima, e.g. overly large LSTMs (Zaremba et al., 2014) show marked improvements in performance; (c) regularization choices are necessary to find good solutions for different model parameterizations, e.g. experiments by Merity et al. (2017) outline a variety of training choices.

In this work, we revisit HMMs for language modeling, positing that competitive performance requires very large HMM (VL-HMMs). To scale to large state-spaces, we need shared parameterizations, efficient inference, and effective regularization. We develop a neural parameterization for HMMs that extends them to comparable size and structure of deep models. We combine this parameterization with a modeling constraint that allows us to utilize HMMs with very large state spaces, while maintaining efficient exact inference. Finally we incorporate a variant of dropout that both improves accuracy and reduces the computational overhead by an order of magnitude during training.

Experiments employ VL-HMMs on two language modeling datasets. We find that our HMM extension significantly outperforms past HMMs as well as n-gram models. It also performs comparably to neural counterparts with a similar number of parameters while maintaining uncertainty over the state dynamics.

2 Related Work

Several recent papers have combined HMMs with neural networks. Buys et al. (2018) develop an approach to relax the HMM with results that either have HMM performance much worse than an n-gram model or require altering the probabilistic structure. Krakovna and Doshi-Velez (2016) utilize

model combination with a recurrent neural network to connect both approaches in a 20 state model. We demonstrate how to scale to orders of magnitude more states and show performance surpassing n-gram models.

Prior work has demonstrated the benefits of neural parameterization of structured generative models. For HMMs, [Tran et al. \(2016\)](#) demonstrate improvements in POS induction with a neural parameterization of an HMM. Other work has used neural parameterization for classic models, such as dependency models with valence ([Han et al., 2017](#)), hidden semi-Markov models ([Wiseman et al., 2018](#)), and context free grammars ([Kim et al., 2019](#)). All of these works use latent variables with relatively small state spaces, as the goal of both was structure induction rather than language modeling itself. We extend the neural parameterization with the aim of supervised modeling.

Finally, another approach to scaling to larger state spaces is to initialize with a small state space then grow the state space via a split-merge process ([Petrov et al., 2006](#); [Huang, 2011](#)). In particular, [Huang \(2011\)](#) learn an HMM for language modeling via this process. The application of more complicated split-merge procedures is an avenue for future work, as we focus on fixed-size state spaces.

3 Background: HMMs

We are interested in learning a distribution over observed tokens $\mathbf{x} = \langle x_1, \dots, x_T \rangle$, with each token x_t an element of the finite vocabulary \mathcal{X} . Hidden Markov models (HMMs) specify a joint distribution over observed tokens \mathbf{x} and discrete latent states $\mathbf{z} = \langle z_1, \dots, z_T \rangle$, with each z_t from finite set \mathcal{Z} . For notational convenience, we define the starting state $z_0 = \epsilon$. This yields the joint distribution

$$p(\mathbf{x}, \mathbf{z}; \theta) = \prod_{t=1}^T p(x_t | z_t) p(z_t | z_{t-1}) \quad (1)$$

The distributions are parameterized as follows

$$p(z_t | z_{t-1}) \propto e^{\psi_{z_t z_{t-1}}} \quad p(x_t | z_t) \propto e^{\phi_{x_t z_t}} \quad (2)$$

with transitions $\psi \in \mathbb{R}^{|\mathcal{Z}| \times |\mathcal{Z}|}$ and emissions $\phi \in \mathbb{R}^{|\mathcal{X}| \times |\mathcal{Z}|}$. We refer to $p(z_t | z_{t-1})$ as \mathbf{T} and $p(x_t | z_t)$ as \mathbf{O} .

We distinguish two types of parameterizations: *scalar* and *neural*. A scalar parameterization simply uses $\theta = \{\phi, \psi\}$ to fit one model parameter for

Figure 1: HMM search space after applying emission sparsity constraints and the state dropout method.

each distributional parameter ($O(|\mathcal{Z}|^2 + |\mathcal{X}||\mathcal{Z}|)$ model parameters). A neural parameterization uses θ as the parameters of a neural network that generates ϕ and ψ for the distribution, which allow for task based factorization.

In order to fit an HMM to data \mathbf{x} , we must marginalize over the latent states to obtain the likelihood $p(\mathbf{x}) = \sum_{\mathbf{z}} p(\mathbf{x}, \mathbf{z})$. This sum can be computed in time $O(T|\mathcal{Z}|^2)$ via dynamic programming, which becomes prohibitive if the number of latent states $|\mathcal{Z}|$ is large. We can then optimize the likelihood with gradient ascent (or alternative variants of expectation maximization).

HMMs and RNNs Recurrent neural networks (RNNs) do not attempt to decouple the latent dynamics from the observed. This often leads to improved accuracy, but does not allow for posterior inference or for directly incorporating additional state information. A further benefits of HMMs is that, unlike RNNs, their associative structure allows for parallel inference via the prefix-sum algorithm ([Ladner and Fischer, 1980](#)).¹

4 Scaling HMMs

Blocked Emissions Marginal inference for HMMs is quadratic in the size of the state space $|\mathcal{Z}|$, which inherently limits their representational capacity. However, we can improve the complexity in special cases. For instance, inspired by cloned

¹Quasi-RNNs ([Bradbury et al., 2016](#)) also have a logarithmic dependency on T by applying the same prefix-sum trick, but do not model uncertainty over latent dynamics.

HMMs (Dedieu et al., 2019) if we know that the probability of emitting a word x_t from a state z_t is 0, i.e. $p(x_t | z_t) = 0$ then we can ignore transitions into and from that state during inference.

We enforce a stronger constraint that the HMM have rectangular fixed-width blocked emissions,

$$\mathbf{O} = \begin{bmatrix} \mathbf{O}^1 & 0 & 0 \\ 0 & \dots & 0 \\ 0 & 0 & \mathbf{O}^M \end{bmatrix}$$

where each $\mathbf{O}_m \in \mathbb{R}^{\mathcal{X}_m \times |\mathcal{Z}|/M}$ is a partition indicating which tokens \mathcal{X}_m can be emitted by states $m|\mathcal{Z}|$ through $(m+1)|\mathcal{Z}|$. Conversely let $\mathcal{Z}_x \subset \mathcal{Z}$ be the states with non-zero probability of emitting x .

Our parameterization is chosen to ensure this property holds.

Exact marginalization can be computed as

$$\begin{aligned} p(\mathbf{x}) &= \sum_{z_1 \in \mathcal{Z}_{x_1}} p(z_1 | z_0) p(x_1 | z_1) \times \\ &\dots \sum_{z_T \in \mathcal{Z}_{x_T}} p(z_T | z_{T-1}) p(x_T | z_T) \end{aligned} \quad (3)$$

This gives a serial complexity of $O(T(|\mathcal{Z}|/M)^2)$

Factored Neural Parameterization Even with blocked emissions, the scalar parameterization of an HMM grows quadratically with states due to the transition matrix. We instead employ a neural parameterization. The approach is to embed each state in \mathcal{Z} ($\mathbf{E}_z \in \mathbb{R}^{|\mathcal{Z}| \times h}$), each token in \mathcal{X} ($\mathbf{E}_x \in \mathbb{R}^{|\mathcal{X}| \times h}$), and each partition ($\mathbf{E}_\pi \in \mathbb{R}^{M \times h}$). From these we can create representations for leaving a state, entering a state, and emitting a word:

$$\mathbf{H}_{\text{out}}, \mathbf{H}_{\text{in}}, \mathbf{H}_{\text{emit}} = \text{MLP}(\mathbf{E}_\pi, \mathbf{E}_z)$$

The HMM distributional parameters are given by,

$$\phi = \mathbf{E}_x \mathbf{H}_{\text{emit}}^\top \quad \psi = \mathbf{H}_{\text{out}} \mathbf{H}_{\text{in}}^\top \quad (4)$$

where $\phi \in \mathbb{R}^{|\mathcal{X}| \times |\mathcal{Z}|}$ and $\psi \in \mathbb{R}^{|\mathcal{Z}| \times |\mathcal{Z}|}$. The MLP architecture follows (Kim et al., 2019). Please refer to the supplementary material for details. This neural parameterization takes $O(h^2 + h|\mathcal{Z}| + h|\mathcal{X}|)$ parameters.

Note that parameter computation is independent of inference and can be cached at test-time. For training, we compute them once per batch. For RNNs and similar models, emission probabilities must be recomputed for each token.

Algorithm 1 VL-HMM Training

Given: block structure and model parameters

Sample block-wise dropout mask \mathbf{b}

Compute ϕ, ψ ignoring $b_z = 0$

for all batch examples \mathbf{x} **do**

$\Phi = \text{LOGPOTENTIALS}(\phi, \psi, \mathbf{x}, \mathbf{b})$

$\log p(\mathbf{x}) = \text{FORWARD}(\Phi)$

Update embeddings $\mathbf{E}_z, \mathbf{E}_x, \mathbf{E}_\pi$

Dropout as State Reduction To encourage generalization through distributed state usage, we introduce dropout to the model. We propose a form of HMM state dropout that removes states from use entirely, which has the added benefit of speeding up inference.

State dropout acts on each emission block $\mathbf{O}_1 \dots \mathbf{O}_M$ independently. Recall each block has $|\mathcal{Z}|/M$ columns. For each, we sample a binary dropout mask by sampling $\lambda_{\text{drop}} \times (|\mathcal{Z}|/M)$ dropped row indices uniformly without replacement. We concatenate these to a global vector \mathbf{b} , which, along with the previous constraints, ensures,

$$p(x | z) \propto b_z 1(z \in \mathcal{Z}_x) e^{\phi_{xz}} \quad (5)$$

State dropout gives a larger practical speed up for both parameter computation and inference. For a dropout factor of 0.5 we get a $4\times$ speed improvement for both, due to reduction of possible transitions. This structured dropout is also easier to exploit on GPU, since it maintains block structure with fixed-height.

5 HMM Language models

In this section we provide further details on the application of the methods described in the previous section to word-level language modeling, where the tokens \mathbf{x} correspond to the words $\mathbf{w} = \langle w_1, \dots, w_T \rangle$ in a sentence. We thus learn a model over words and states $p(\mathbf{w}, \mathbf{z}) = \prod_t p(w_t | z_t) p(z_t | z_{t-1})$.

State and word partitions We use Brown clusters (Brown et al., 1992; Liang, 2005) to construct the state and word partitions. Brown clusters are obtained by assigning every token type in \mathcal{X} a state in a HMM, then states are merged until a desired number of states M is reached. Importantly, every word is emit by only a single state, giving us the

word partitions \mathcal{X}_m . We then clone the states of the Brown HMM $|\mathcal{Z}|/M$ times to obtain the \mathcal{Z}_x .

5.1 Datasets

We evaluate on the Penn Treebank (Marcus et al., 1993) and wikitext2 (Merity et al., 2016) datasets. Penn Treebank contains 929k tokens in the training corpus, with a vocabulary size of 10k. We use the preprocessing from Mikolov et al. (2011), which lowercases all words and substitutes words outside of the vocabulary with unks. Wikitext2 contains 2M tokens in the training corpus, with a vocabulary size of 33k. Casing is preserved, and all words outside the vocab are replaced with the unk token. Both datasets contain inter-sentence dependencies, due to the use of documents consisting of more than a single sentence.

We construct the Brown clusters on the training portions of both datasets. As baselines, we train a 5-gram model (Heafield et al., 2013), a feedforward model with 256 hidden dimensions, and a 2-layer LSTM with 256 hidden dimension. We compare these models with an HMM that considers 256 latent states at every timestep at test time.

6 Results

6.1 Language Modeling

We report perplexities for Penn Treebank in Table 1 and for Wikitext-2 in Table 2.

On Penn Treebank, we see in Tbl. 1 that a 32k state HMM is able to outperform the n-gram models as reported by Mikolov and Zweig (2012), achieving a test perplexity of 115.8 versus 141.2 respectively.

We also find that the 32k state HMM vastly outperforms the vanilla HMM results from Buys et al. (2018), which achieved a validation perplexity of 284.6² versus the 32k state HMM at 125.0. The 32k state HMM outperforms their HMM extension, which achieves a validation perplexity of 142.3 by relaxing various HMM assumptions to more closely resemble an RNN.

However, we find that the HMM underperforms RNN-based models. The baseline 2-layer 256 dim LSTM achieves 88.8 test perplexity, beating the HMM by 27 ppl. This trend persists in Wikitext-2, with the HMM outperforming the

²Buys et al. (2018) did not report test perplexity in their experiments.

Figure 2: Perplexities on the Penn Treebank dataset as a function of the state size $|\mathcal{Z}|$. We hold the emission constraints fixed using 128 Brown clusters, and state dropout at 0.5.

5-gram model at **FILL IN** and 210.9 perplexity respectively.

In the remainder of this section we ablate and analyze the HMMs on Penn Treebank.

Number of states In Tbl. 2 we examine the effect of the number of states on perplexity. We find that performance continuously improves as we increase the size of the state space, up until we reach 65k states. It is possible that at 65k states, we are bottlenecked by other aspects of the model, such as the expressive power or learnability of the neural parameterization. However, we note that increasing the dimension of the neural component from 256 to 512 dimensions with $|\mathcal{Z}| = 32,768$ total states did not improve performance. Another hypothesis is that the marginal gains in likelihood decreases as we continue to increase the size of the state space.

Emission constraint ablation We next analyze the effect of the emission constraint and dropout on performance. We fix the total number of states at 16k and vary the emission constraints and dropout rate. In the top section of Tbl. 3, we find that the performance is insensitive to the number of Brown clusters at 16k states. However, in the middle section, the model is sensitive to the number of Brown clusters at 1k total states. The 1k state HMM with 4 Brown clusters matches the unconstrained 1k state HMM, while the HMM with 8 Brown clusters underperforms. This implies that there may be a loss in performance due to the emission constraints.

We additionally compare the partition induced by Brown clustering with a uniform constraint that

Model	Num Params	Valid PPL	Test PPL
KN-5 (Mikolov and Zweig, 2012)	2M	-	141.2
RNN (Mikolov and Zweig, 2012)	2M	-	124.7
Medium LSTM (Zaremba et al., 2014)	20M	86.2	82.7
Large LSTM (Zaremba et al., 2014)	66M	82.2	78.4
AWD-LSTM (Merity et al., 2017)	24M	60.0	57.3
HMM (Buys et al., 2018)	10M	284.6	-
HMM + sigmoid + RNN emit (Buys et al., 2018)	10M	142.3	-
256 dim FF 5-gram	2.9M	159.9	152.0

32k state HMM	7.7M	125.0	115.8

Table 1: Perplexities on the Penn Treebank dataset. The bottom section shows results for models with comparable computational cost. In particular, we compare models that have the same asymptotic inference cost: linear in the length of a sequence and quadratic in the hidden dimension. This is $h = 256$ for the FF model and LSTM and $|\mathcal{Z}| = 256$ for the HMM.

Model	Num Params	Valid PPL	Test PPL
AWD-LSTM (Merity et al., 2017)	33M	68.6	65.8
AWD-LSTM-MoS (Yang et al., 2017)	35M	63.9	61.5
AWD-LSTM-DOC (Takase et al., 2018)	37M	60.3	58.0
KN-5	5.7M	248.7	234.3
256 dim FF 5-gram	8.8M	210.9	195.0
2 layer 256 dim LSTM	9.6M	124.5	117.5
32k state HMM	13.7M	-	-

Table 2: Single model perplexities on the Wikitext-2 dataset. The bottom shows results for the models with similar computation cost, using the same hyperparameters applied to Penn Treebank.

samples each \mathcal{C}_x of size n independently and uniformly from all subsets of \mathcal{C} . This foregoes a partitioning, which makes it difficult to apply state dropout. We therefore apply a version of dropout that does not have block structure and zeroes out elements of the transition matrix randomly. In the bottom section of Tbl. 3, we find that models with uniform constraints are consistently outperformed by models with Brown cluster constraints as measured by validation perplexity. The models with uniform constraints also had poor validation perplexities despite better training perplexities, a symptom of overfitting.

In conclusion, we find the Brown cluster emission constraints to achieve reasonable performance in HMMs with large state spaces. We also observe that model performance is sensitive to the emission constraints, motivating future work towards exploring learning emission constraints while keeping inference tractable.

Dropout and parameterization ablation We ablate state dropout and model parameterization in Tbl. 4. We find that state dropout results in both an improvement in perplexity and a large improvement in time per epoch. The train-val gap for the model without state dropout was much larger than the model with dropout, highlighting the effectiveness of state dropout as regularization.

The scalar parameterization, which was run with 0.5 state dropout, has a massive number of model parameters at 423M, compared to the neural parameterization with 5.6M parameters. Although the neural and scalar parameterizations reach a similar training perplexity, the neural model generalizes better on validation.

We additionally ablate the factored state embeddings, and find that the performance of state embeddings with independent parameters is similar to a model with factored embeddings. We additionally found that if the number of clusters is too small (i.e. 64 or 32 as opposed to 128) while keeping the total

Constraint	$ \mathcal{Z} $	$ \mathcal{C}_x $	m	Val PPL
